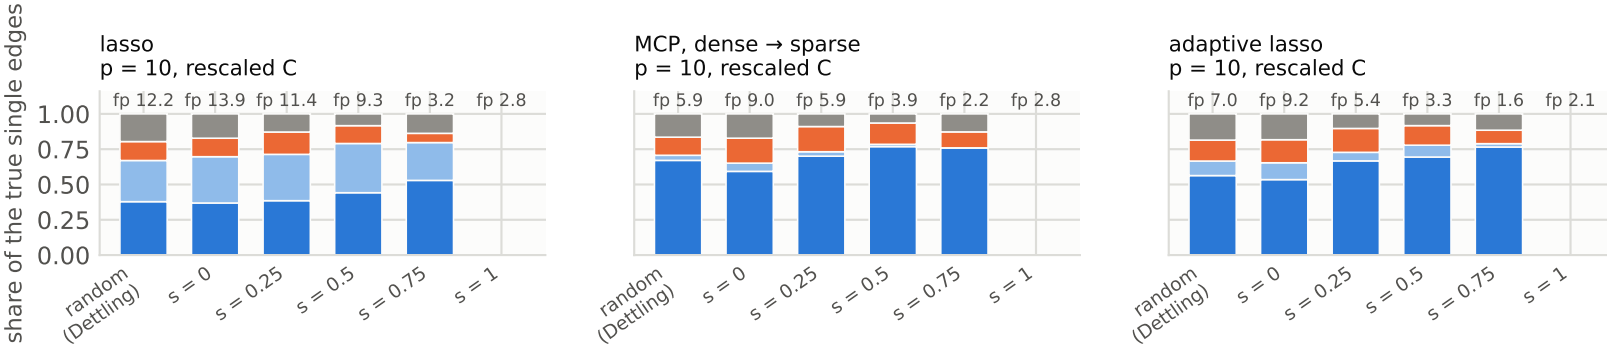
E5: the share of 2-cycles as a knob, direct loss -- the true single edges in the selected graph (eBIC, γ = 0.5), n = 10⁴ (fp: false positives per graph)
[laptop rehearsal: p = 10, true C = 2I, 4 replicates, 16 graphs per cell]



Graph per data set: the support recovered by eBIC, partitioned by how the edges kept (the hedges) split between the true direction and the reverse, plus the true edges missed (outside 2-cycles) of a graph by their fate and always sums to one; it is the mean over the cell's graphs of those shares. The estimated graph's size is not shown: fp = its false positives per graph (hedges + reversals + edges between unconnected nodes).
